Abstract. The global properties of the classical three-dimensional Lotka-Volterra two prey-one predator and one prey-two predator systems, under the assumption that competition can be neglected, are analysed with the direct Lyapunov method. It is shown that, except for a pathological case, one species is always driven to extinction, and the system behaves asymptotically as a two-dimensional predator-prey Lotka-Volterra system. The same approach can be easily extended to systems with many prey species and one predator, or many predator species and one prey, and the same conclusion holds. The situation considered is common for New Zealand wildlife, where indigenous and introduced species interact with devastating consequences for the indigenous species. According to our results the New Zealand indigenous species are definitely driven to extinction, not only in consequence of unsuccessful competition, but even when competition is absent. This result leads to a better understanding of the mechanism of natural selection, and gives a new insight into pest control practice.

Keywords: Lotka-Volterra systems, Lyapunov functions.

1. Introduction

One of the most commonly used models of predator-prey interaction is the classical Lotka-Volterra predator-prey model

\[ \begin{align*}
\dot{x} &= x(a - by), \\
\dot{y} &= y(-c + dx), \\
(\dot{x} &\equiv \frac{dx}{dt}, \dot{y} \equiv \frac{dy}{dt})
\end{align*} \]  

(1)

where \( x(t), y(t) \) are the prey and predator population biomass at time \( t \); \( a, b, c, d \) are positive constants. Phase curves of (1) form the family of closed curves, given by the first integral

\[ U = dx - c \ln x + by - a \ln y, \]  

(2)

around the neutrally-stable steady-state \( (c/d, a/b) \).

The Lotka-Volterra model indeed may be the simplest possible predator-prey model. It has been criticised as being unrealistic—mainly for its structural instability and the assumption of the unlimited growth of the prey population \( x(t) \) in the
absence of a predator. Nevertheless, it is a useful tool containing the basic properties of the real predator-prey systems, and serves as a robust basis from which it is possible to develop more sophisticated models.

The model (1) can be naturally generalised for the multi-species case. The generalisation of the Lotka-Volterra model (1) for the multi-species case retains the basic features of real ecological systems and, as will be shown, allows us to obtain valuable results that are easy to be interpreted. For the three-species predator-prey interaction two possibilities arise: the two prey-one predator system

\[ \begin{align*}
\dot{x}_1 &= x_1(a_1 - b_1 y) , \\
\dot{x}_2 &= x_2(a_2 - b_2 y) , \\
y &= y(-c + d_1 x_1 + d_2 x_2),
\end{align*} \tag{3} \]

and a two predator-one prey system

\[ \begin{align*}
\dot{x} &= x(a - b_1 y_1 - b_2 y_2) , \\
\dot{y}_1 &= y_1(-c_1 + d_1 x) , \\
\dot{y}_2 &= y_2(-c_2 + d_2 x). 
\end{align*} \tag{4} \]

Here \( x_1, x_2 \) are prey populations, \( y_1, y_2 \) are predator populations, and \( a_i, b_i, c_i, d_i \) are positive constants.

The equations (3) assume that the prey populations \( x_1, x_2 \) have not reached, and are not able to reach, their media capacity because of predation or for some other reasons, and that interspecies competition is absent or negligible. These situations (the absence of the direct competition between two prey species having a common predator) are not common but they are not unrealistic, and, we are sure, have arisen repeatedly in the past in the process of evolution. As a result of the artificial introduction of alien species there are some examples of such systems in New Zealand. The interaction of kiwi—rabbits—stoats is an example. Occupying different ecological niches (bush for the kiwi and open fields for rabbits), the rabbits and kiwi do not compete. The populations of the both species are far from reaching their media capacity as a result of predation and artificial controlling of the rabbit population. Furthermore, both the kiwi and the rabbits have the same predators: stoats, cats, minks, or any others. Hence, the kiwi—rabbit—stoat interaction can be adequately described by the equations (3).

The equations (4) describe the situation when two predator species depend on a common prey and, furthermore, these two predator species do not interact directly, they do not fight directly (not usually, at least), do not predate one the other, and do not depend one on the other as a food source. Such situations are not unusual, and can arise in many different cases.

The multi-species Lotka-Volterra predator-prey systems have been studied by many authors. In the early papers, such as [1], [2], [4], [8], [9] and others, the influence of the predation on the two competing species was studied, and showed that the presence of a predator may stabilise the ecological system which is otherwise unstable. In a number of recent papers, such as [3], [5], [6], [7], the stability and the global dynamical properties of the multi-species Lotka-Volterra systems have been studied. The most complete list of references can be found in Y.Takeuchi’s book [7].
The main aim of this work is to demonstrate that predation may destabilise a comparatively stable system, and that species can be completely annihilated during a finite time as a result of predation only, without any competition at all. Or, in contrast, an unsuccessful predator can be driven to extinction in finite time even without any direct competition. This result leads to a new insight into the mechanism of natural selection.

**Lemma 1** The systems (3) and (4) are equivalent under inversion of time $t$.

The proof is straightforward with substitution of $\tau = -t$ in (3) or (4). The lemma makes it possible to apply the same methods to both systems (3) and (4).

We call the parameter $r_i = a_i/b_i$ for the prey $x_i$, and the parameter $q_i = d_i/c_i$ for the predator $y_i$, the capacity to survive, or the survival capacity.

In the regular case, provided by $p_1 \neq p_2$ for (3) and $q_1 \neq q_2$ for (4), each of the systems (3), (4) has three equilibria: the trivial one at the origin and two others on the coordinate planes $x_iy$ or $y_iy$ (the coexisting equilibria of the reduced two-dimensional predator-prey systems), given by $(c/d, 0, p_1)$, $(0, c/d, p_2)$ for (3), and by $(q_1^{-1}, a/b_1, 0)$, $(q_2^{-1}, 0, a/b_2)$ for (4). There are no coexisting equilibria in the regular cases. In the pathological case, provided by $p_1 = p_2$ for (3), or $q_1 = q_2$ for (4), both systems (3), (4) have a continuum of equilibria—the straight line given by $\left(x_1, \frac{c-d_1}{d_1}, p_1\right)$ for (3), or by $\left(q_1^{-1}, y_1, \frac{a-b_1}{b_2}\right)$ for (4), in addition to the trivial equilibrium at the origin.

The phase space of (3) is the positive octant

$$R_+^3 = \{(x_1, x_2, y) \in R^3 | x_1 \geq 0, x_2 \geq 0, y \geq 0\},$$

the phase space of (4) is the positive octant

$$R_+^3 = \{(x, y_1, y_2) \in R^3 | x \geq 0, y_1 \geq 0, y_2 \geq 0\},$$

and their coordinate planes cannot be crossed by any trajectory. Hence the two-dimensional coordinate planes in $R^3$ are the invariant sets of the systems (3) and (4), so a solution of (3) or (4) with positive initial value remains in the positive octant $R_+^3$ forever.

2. Main results

**Theorem 1** The solutions of (3) with positive initial values are bounded, and, if $p_1 > p_2$, then $\lim_{t \to \infty} x_2 = 0$. If $p_1 = p_2$ then (3) has two independent first integrals.

**Proof:** For the case $p_1 \geq p_2$ consider two Lyapunov functions

$$H = \frac{d_1 x_1}{b_1} + \frac{d_2 x_2}{b_2} + y - \frac{c}{b_1} \ln x_1 - \frac{a_1}{b_1} \ln y,$$

(5)
The function $H(x_1, x_2, y)$ satisfies

$$H = (p_2 - p_1)d_2 x_2.$$  
(7)

The condition $p_1 > p_2$ implies that $H < 0$ when $x_2 > 0$, and $H = 0$ when $x_2 = 0$. Hence there is no flux through the coordinate plane $x_2 = 0$; $H < 0$ implies that the phase curve of (3) initiating in the positive octant $R^3_+$ remains forever in the part of $R^3_+$ bounded by the surface $H(x_1, x_2, y) = H(x_1(0), x_2(0), y(0))$ and the plane $x_2 = 0$, and is attracted by the coordinate plane $x_2 = 0$.

If $p_1 = p_2$ then $H \equiv 0$, and $H(x_1, x_2, y)$ is the first integral of (3).

The function $V(x_1, x_2, y)$ satisfies

$$V = (a_2 b_1 - a_1 b_2) V = b_1 b_2 (p_2 - p_1) V \equiv \Delta V,$$
which has the solution

$$V(t) = V(0) e^{\Delta t}.$$  
(8)

So the asymptotic behaviour of $V(t)$ depends upon the sign and value of

$$\Delta = (p_2 - p_1) b_1 b_2.$$

If $p_1 > p_2$, then $\Delta < 0$, and $\lim_{t \to \infty} V = 0$. Since the solution is bounded it implies

$$\lim_{t \to \infty} x_2 = 0.$$

If $p_1 = p_2$ then $V \equiv 0$, and $V(x_1, x_2, y) = constant$ is the first integral of (3). Obviously, $V(x_1, x_2, y)$ and $H(x_1, x_2, y)$ are independent.

This completes the proof. 

By putting $x_2 = 0$ into (5) then the equation $H = constant$ is equivalent to the first integral (2) for the two-dimensional system $(x_1(t), y(t))$. The Lyapunov function of the form (5) has been used by B.-S.Goh [3], Y.Takeuchi [7] and the others.

In the case $p_1 < p_2$ it suffices to change subscripts. The following theorem for the system (4) is the analogue of Theorem 1. The proof follows from Lemma 1, or two Lyapunov functions

$$G = x - c_1 \ln x + \frac{b_1}{d_1} y_1 + \frac{b_2}{d_2} y_2 - \frac{a}{d_1} \ln y_1,$$
$$W = \frac{y_2^{d_1}}{y_1^{d_2}}.$$  

may be considered.

**Theorem 2** The solutions of (4) with positive initial values are bounded, and, if $q_1 > q_2$, then $\lim_{t \to \infty} y_2 = 0$. If $q_1 = q_2$ then (4) has two independent first integrals.

In the biological context there is a critical value $\bar{x}_i$ for a population $x_i(t)$ such that the species is effectively extinct if $0 < x_i(t) < \bar{x}_i$. (If $x_i(t)$ is the number of the
THREE-DIMENSIONAL PREDATOR-PREY SYSTEMS

animals then \( \bar{x}_i = 1 \).

Theorems 1 and 2 imply that for the systems (3), (4) this limit can be reached in finite extinction time \( t_k \). Equation (8) allows us to evaluate the extinction time for the species \( x_i(t) \). Assuming \( p_1 > p_2 \) then for the system (3) \( \lim_{t \to \infty} x_2(t) = 0 \). If the initial values \( x_1(0), x_2(0) \) are given, and assuming \( x_1(t_k) = x_1(0), \) and \( x_2(t_k) = \bar{x}_2 \) then, according to (8),

\[
t_k = \frac{1}{\Delta} \ln \frac{V(t_k)}{V(0)} = \ln \frac{x_2(0)}{\ln \frac{p_1}{p_2} b_2}.
\]

3. Generalisation for \( n + 1 \)-dimensional systems

The system with \( n \) prey and one predator, with the assumption that the interactions between the prey species are negligible, may be described by the equations

\[
\begin{align*}
\dot{x}_1 &= x_1(a_1 - b_1 y), \quad \ldots, \quad \dot{x}_n &= x_n(a_n - b_n y), \\
y &= -c + \sum_{i=1}^{n} d_i x_i.
\end{align*}
\]

The order of the subscripts for (9) is chosen so that \( p_1 > p_2 > \ldots > p_n \), where \( p_i = a_i / b_i \) is the survival capacity of \( x_i \). The following extension of Theorem 1 holds for (9).

Theorem 3 The solutions of (9) with positive initial values are bounded, and, if \( p_1 = p_2 = \ldots = p_m > \max(p_{m+1}, \ldots, p_n) \), then (9) has \( m - 1 \) independent first integrals, and \( \lim_{t \to \infty} x_i = 0 \) for all \( i \geq m + 1 \).

If \( p_1 > \max(p_2, \ldots, p_n) \), then \( \lim_{t \to \infty} x_i = 0 \) for all \( i \geq 2 \).

Proof: Define a Lyapunov function

\[
H(x_1, \ldots, x_n, y) = \sum_{i=1}^{n} \frac{d_i}{b_i} x_i + y - c \ln x_1 - \frac{a_1}{b_1} \ln y.
\]

The derivative of \( H \) along a solution of (9) satisfies

\[
\dot{H} = \sum_{i=1}^{n} \left( \frac{a_i}{b_i} - \frac{a_1}{b_1} \right) d_i x_i = \sum_{i=1}^{n} (p_i - p_1) d_i x_i.
\]

If \( p_1 = p_2 = \ldots = p_m > \max(p_{m+1}, \ldots, p_n) \) then \( \dot{H} < 0 \) until \( x_i = 0 \) for all \( i \geq m \). Since there is no flux through the coordinate planes \( x_i = 0, \ i = 1, \ldots, n \) then the equation (10) implies that the phase curve of (9) with a positive initial value remains forever in the area of \( \mathbb{R}^{n+1}_+ \) bounded by the surface \( H(x_1, \ldots, x_n, y) = H(x_1(0), \ldots, x_n(0), y(0)) \), and the \( n - m \) coordinate planes \( x_i = 0, \ i = m + 1, \ldots, n \).

If \( m = n \) (that is \( p_1 = p_2 = \ldots = p_n \)), then the equation \( H(x_1, \ldots, x_n, y) = \text{constant} \) is the first integral of (9).

Define further \( n(n-1)/2 \) Lyapunov functions
V_{ij} = \frac{x_i^{b_j}}{x_i^{a_j}}

where i < j. For every V_{ij} we have

\dot{V}_{ij} = (a_j b_i - a_i b_j) V_{ij} = b_i b_j (p_j - p_i) V_{ij} = \Delta_{ij} V_{ij}. \tag{11}

Consequently

V_{ij}(t) = V_{ij}(0) \exp(\Delta_{ij} \cdot t). \tag{12}

Since p_1 = p_2 = \ldots = p_m > \max(p_{m+1}, \ldots, p_n), (12) implies that if i \leq m, j > m, then \lim_{t \to \infty} V_{ij} = 0. Consequently, since the solutions are bounded, this implies that \lim_{t \to \infty} x_j(t) = 0.

Since p_1 = p_2 = \ldots = p_m, all m(m - 1)/2 equations \dot{V}_{ij}(x_i, x_j) = constant, where i < j \leq m, are the first integrals of (9). It is easy to show that m - 1 independent first integrals, for instance \dot{V}_{ij}(x_1, x_j), j = 2, \ldots, n, may be chosen among them.

This completes the proof.

The system with one prey and n predators, and with the assumption that direct interspecies competition between the predators is negligible, may be described by the equations

\dot{x} = x (a - \sum_{i=1}^{n} b_i y_i),
\dot{y}_1 = y_1 (-c_1 + d_1 x), \ldots, \dot{y}_n = y_n (-c_n + d_n x). \tag{13}

The order of the subscripts for (13) is chosen so that q_1 \leq q_2 \leq \ldots \leq q_n, where q_i = d_i/c_i is the survival capacity of y_i. Then the extension of Lemma 1 holds for (9) and (13).

**Lemma 2** The systems (9) and (13) are equivalent under inversion of time t.

The proof is straightforward, and we omit it here.

The following extension of Theorem 2 to the system (13) is the direct consequence of Theorem 3 and Lemma 2.

**Theorem 4** The solutions of (13) with positive initial values are bounded, and, if q_n = q_{n-1} = \ldots = q_{n-m+1} > \max(q_1, \ldots, q_{n-m}), then (13) has m - 1 independent first integrals, and \lim_{t \to \infty} y_i = 0 for all i \leq n - m.

If q_n > \max(q_1, \ldots, q_{n-1}), then \lim_{t \to \infty} y_i = 0 for all i < n.

The proof is analogous to that of Theorem 3.

4. Discussion

The results of this paper demonstrate that, under the assumptions made, a biological species may be eliminated (effectively in finite time). A herbivorous species
can be eliminated by predation if there is another herbivorous species with a higher survival capacity and which provides a predator with a permanent food base, even if there is no direct competition between these two herbivorous species. An unsuccessful predator will be eliminated in finite time if there is another predator with higher survival capacity. The results lead to the conclusion that predation, not competition only, is responsible for extinction of some species in the process of evolution.

It has been mentioned already that, as a consequence of the artificial introduction of alien species into New Zealand, there are some examples of the systems considered in this paper. Our results lead to the unfavourable conclusion that the New Zealand indigenous species are definitely driven to extinction, not only in consequence of unsuccessful competition, but even when competition is absent. For example, in the above-mentioned case (kiwi—rabbits—stoats system) the kiwi may be completely eliminated in finite time by predation alone.

The results in this paper suggest a new approach to a problem of a pest control. Usually biological pest control requires the introduction of a predator decreasing the pest population to an acceptable level. This approach provides only a short term result as after some time this predator-prey system has reached its coexisting equilibrium. According to our results, pest control would be much more effective if, simultaneously with the introduction of predators, a prey species is introduced to provide the predators with a long-term food base. It is not necessary for the introduced prey to compete with the pest for resources. It is even better if they do not compete, as the resources can be the subject of protection. But the introduced prey species must have a higher survival capacity than the pest has. Under these circumstances, the original pest species will be completely annihilated in finite time. Of course, the introduced alternative prey should be harmless or less harmful than the original one.

Though the analysis in this paper uses the simplest predator-prey model an interesting biological result have been derived. Consequently, it will be worthwhile to examine the robustness of this result in more detailed models.

Special Issue on
Intelligent Computational Methods for
Financial Engineering

Call for Papers

As a multidisciplinary field, financial engineering is becoming increasingly important in today's economic and financial world, especially in areas such as portfolio management, asset valuation and prediction, fraud detection, and credit risk management. For example, in a credit risk context, the recently approved Basel II guidelines advise financial institutions to build comprehensible credit risk models in order to optimize their capital allocation policy. Computational methods are being intensively studied and applied to improve the quality of the financial decisions that need to be made. Until now, computational methods and models are central to the analysis of economic and financial decisions.

However, more and more researchers have found that the financial environment is not ruled by mathematical distributions or statistical models. In such situations, some attempts have also been made to develop financial engineering models using intelligent computing approaches. For example, an artificial neural network (ANN) is a nonparametric estimation technique which does not make any distributional assumptions regarding the underlying asset. Instead, ANN approach develops a model using sets of unknown parameters and lets the optimization routine seek the best fitting parameters to obtain the desired results. The main aim of this special issue is not to merely illustrate the superior performance of a new intelligent computational method, but also to demonstrate how it can be used effectively in a financial engineering environment to improve and facilitate financial decision making. In this sense, the submissions should especially address how the results of estimated computational models (e.g., ANN, support vector machines, evolutionary algorithm, and fuzzy models) can be used to develop intelligent, easy-to-use, and/or comprehensible computational systems (e.g., decision support systems, agent-based system, and web-based systems).

This special issue will include (but not be limited to) the following topics:

- **Application fields**: asset valuation and prediction, asset allocation and portfolio selection, bankruptcy prediction, fraud detection, credit risk management
- **Implementation aspects**: decision support systems, expert systems, information systems, intelligent agents, web service, monitoring, deployment, implementation

Authors should follow the Journal of Applied Mathematics and Decision Sciences manuscript format described at the journal site http://www.hindawi.com/journals/jamds/.
