Variable Transformations for Nearly Singular Integrals in the Boundary Element Method

Dedicated to Professor Masao Iri and Professor Masatake Mori

By

Ken HAYAMI*

§1. Introduction

The Boundary Element Method (BEM) or the Boundary Integral Equation (BIE) method is a convenient method for solving partial differential equations, in that it requires discretization only on the boundary of the domain [2].

In the method, the accurate and efficient computation of boundary integrals is important. In particular, the evaluation of nearly singular integrals, which occur when computing field values near the boundary or treating thin structures, is not an obvious task.

For this purpose, Lachat and Watson [25] proposed an adaptive element subdivision method using an error estimator for the numerical integration. Later, a more sophisticated variable order composite quadrature with exponential convergence was proposed by Schwab [27].

A different approach using quadratic and cubic variable transformations in order to weaken the near singularity before applying Gauss quadrature was introduced by Telles [29]. Koizumi and Utamura [20, 21] used polar coordinates with corrections. Hackbusch and Sauter [7] also used local polar coordinates, performing the inner integrals analytically and the outer integral by Gauss quadrature.

Another approach is to subtract out the near singularity using analytical integration formulas for constant planar elements, and then evaluating the

remainder term using Gauss quadrature as in Cruse and Aithal [4]. Further, Sládek and Sládek [28] proposed a method to reduce the near singularity of the original boundary integral equation instead of calculating the near singular integral directly.

In this paper, we will review variable transformation methods for evaluating nearly singular integrals over curved surfaces, which were proposed by the author and co-workers [3], [8]-[17], [22]-[24].

The rest of the paper is organized as follows. Section 2 gives a brief explanation of the boundary element formulation of the three-dimensional potential problem. In section 3, we analyze the nature of integral kernels occurring in such a formulation. In section 4, we present the outline of the PART method proposed by the author. In section 5, we treat the radial variable transformation, which is particularly important in the method. In section 6, we perform an error analysis of the method using complex function theory, which yields insight regarding the optimal radial variable transformation. In section 7, we mention the use of the double exponential transformation in the radial variable transformation.

§2. Boundary Element Formulation of 3-D Potential Problems

Let us consider the three-dimensional potential problem as an example. The boundary integral equation is given by

\begin{equation}
    c(x_s)u(x_s) = \int_\Gamma (qu^* - uq^*)d\Gamma
\end{equation}

where \( x_s \) is the source point, \( u(x) \) is the potential, and \( q(x) := \frac{\partial u}{\partial n} \) is the derivative of \( u \) along the unit outward normal \( n \) at \( x \) on the boundary \( \Gamma \). \( \Gamma \) is the boundary of the domain \( \Omega \) of interest, and boundary conditions concerning \( u \) and \( q \) are given on \( \Gamma \). \( c(x_s) = 1 \) when \( x_s \in \Omega \) and \( c(x_s) = \frac{1}{2} \) when \( x_s \in \Gamma \) and \( \Gamma \) is smooth at \( x_s \).

The fundamental solutions \( u^* \) and \( q^* \) are defined by

\begin{equation}
    u^*(x, x_s) = \frac{1}{4\pi r}, \quad q^*(x, x_s) = -\frac{(r, n)}{4\pi r^3}
\end{equation}

where \( r := x - x_s \) and \( r := ||r||_2 \).

The flux at a point \( x_s \in \Omega \) is given by

\begin{equation}
    \frac{\partial u}{\partial x_s} = \int_\Gamma \left( q \frac{\partial u^*}{\partial x} - u \frac{\partial q^*}{\partial x} \right) d\Gamma
\end{equation}
where
\begin{equation}
\frac{\partial u^*}{\partial x_s} = \frac{r}{4\pi r^3}, \quad \frac{\partial q^*}{\partial x_s} = \frac{1}{4\pi} \left\{ \frac{n}{r^3} - \frac{3(r, n) r}{r^5} \right\},
\end{equation}

Equations (2.1) and (2.3) are discretized on the boundary \( \Gamma \) into boundary elements \( S_e \) \((e = 1 \sim N)\) defined by interpolation functions. The integral kernels of equations (2.1) and (2.3) become nearly singular when the distance \( d \) between \( x_s \) and \( S_e \) is small compared to the size of \( S_e \). (In the following, we will denote the boundary element \( S_e \) by \( S \) for brevity.)

§3. Nature of Nearly Singular Integral Kernels in 3-D Potential Problems

First, we will analyze the nature of nearly singular integral kernels occurring in the boundary element formulation of 3-D potential problems. Since near singularity becomes significant in the neighbourhood of the source point \( x_s \), we will take a planar element \( S \) to study the basic nature of the near singular kernels. Let \( x_s \) be the point nearest to \( x_s \) on \( S \). Then, introduce Cartesian coordinates \((x, y, z)\) with \( S \) in the \( xy \)-plane, and polar coordinates \((\rho, \theta)\) in \( S \) centred at \( x_s \).

Since
\begin{equation}
x_s = \begin{pmatrix} 0 \\ 0 \\ d \end{pmatrix}, \quad x = \begin{pmatrix} x \\ y \\ 0 \end{pmatrix} = \begin{pmatrix} \rho \cos \theta \\ \rho \sin \theta \\ 0 \end{pmatrix}, \quad r = \begin{pmatrix} \rho \cos \theta \\ \rho \sin \theta \\ -d \end{pmatrix}, \quad n = \begin{pmatrix} 0 \\ 0 \\ -1 \end{pmatrix},
\end{equation}
and \((r, n) = d\), equations (2.2) and (2.4) can be expressed as
\begin{equation}
u^* = \frac{1}{4\pi r}, \quad q^* = -\frac{d}{4\pi r^3}, \quad \frac{\partial u^*}{\partial x_s} = \frac{1}{4\pi} \left( \frac{\rho \cos \theta}{r^3} \right), \quad \frac{\partial q^*}{\partial x_s} = \frac{1}{4\pi} \left( -\frac{3d \rho \cos \theta}{r^5} - \frac{3d \rho \sin \theta}{r^5} - \frac{1}{r^3} + \frac{3d^2}{r^5} \right).
\end{equation}

For a constant planar element \( S \) we have
\begin{equation}
\int_S dS = \int_0^{2\pi} d\theta \int_0^{\rho_{\text{max}}(\theta)} \rho d\rho
\end{equation}
using the polar coordinates defined above. Hence, the nearly singular integrals in three-dimensional potential problems involving kernels \( u^*, q^*; \frac{\partial u^*}{\partial x_s}, \frac{\partial q^*}{\partial x_s} \) are given in the form
\begin{equation}
\int_0^{2\pi} d\theta \int_0^{\rho_{\text{max}}(\theta)} \frac{\rho^2 d\rho}{r^5}.
\end{equation}
Here

\[ I_{\alpha,\delta} := \int_0^{\rho_j} \frac{\rho^\delta}{\rho^\alpha} d\rho \]

where \( r = r' := \sqrt{\rho^2 + d^2} \) for planar elements, and \( \rho_j = 1 \), for example, can be considered as a model radial variable integral which depicts the essential nature of the nearly singular integrals arising from equations (2.1) and (2.3). The potential integral of equation (2.1) gives rise to \( \alpha = \delta = 1 \) and \( \alpha = 3, \delta = 1 \), whereas the flux integral of equation (2.3) gives rise to \( \alpha = 3, \delta = 1, 2 \) and \( \alpha = 5, \delta = 1, 2 \).

§4. The Projection and Angular & Radial Transformation (PART) Method

As seen in the previous section, nearly singular integrals arising in the three-dimensional boundary element method may be expressed as

\[ I = \int_S \frac{f}{r^\alpha} dS \]

where \( S \) is generally a curved surface patch, \( r = ||x - x_s||_2 \) is the distance between a fixed source point \( x_s \) and a point \( x \) on \( S \). \( \alpha \) is a positive integer and \( f \) is a function of \( x \in S \), which does not have any near singularity in \( r \). The near singularity of the integrand arises from the denominator \( r^\alpha \), when the distance between \( x_s \) and \( S \) is small compared to the size of \( S \), since the value of the integrand may vary rapidly along \( S \) near \( x_s \).

When \( S \) is planar, the integral may have a closed form for some \( f \), but this is not the case when \( S \) is curved.

The present method was motivated by Telles’ method [29], which uses product type Gauss quadrature after applying cubic variable transformations in each of the two variables describing \( S \) in order to weaken the near singularity. Let the source distance \( d \) be the distance between the source point \( x_s \) and \( S \). It was found that Telles’ method does not give accurate results with a reasonable number of quadrature points when \( d \) is less than about 1% compared to the size of \( S \). Another drawback of Telles’ method when applied to integrals over surfaces is that it concentrates the quadrature points towards the two lines, parallel to the axes in the parameter space defining the curved element, passing through the point corresponding to the source projection, since the method uses the product rule in Cartesian coordinates.
Our method is based on the observation that, since the near singularity depends on the distance $||x - x_s||_2$, one should introduce some kind of polar coordinates near $x_s$, and then introduce variable transformation along the radial variable, in order to efficiently weaken the near singularity.

Let a point on the curved element $S$ be described by $x(\eta_1, \eta_2)$. The method consists of the following steps.

1. Find the point $x(\eta_1, \eta_2)$ on $S$ nearest to $x_s$, using Newton-Raphson’s method. Compute the source distance $d := ||x_s - x(\eta_1, \eta_2)||_2$.

2. Determine the point $\tilde{x}_s = \tilde{x}(\eta_1, \eta_2) = \sum_j \tilde{\varphi}_j(\eta_1, \eta_2)x_j$ on the element $\tilde{S}$ which is obtained by connecting the neighbouring corner nodes $x_j$ of the original curved element $S$ by straight lines.

3. Linearly map each sub-triangle $\triangle_j$ in the parameter space $(\eta_1, \eta_2)$, onto the corresponding sub-triangle $\tilde{\triangle}_j$ : $\tilde{x} \in \tilde{\triangle}_j$.

4. Introduce polar coordinates $(\rho, \theta)$ centred at $\tilde{x}_s$ in each sub-triangle $\tilde{\triangle}_j$, to get

$$ I = \sum_j \int_0^{\Delta \theta_j} d\theta \int_0^{\rho_j(\theta)} f J_j \rho d\rho. $$

Here, $J_j$ is the Jacobian of the mapping from Cartesian coordinates on $\tilde{\triangle}_j$ to curvilinear coordinates $(\eta_1, \eta_2)$, $\Delta \theta_j = \angle x_j \tilde{x}_s x_{j+1}$.

$$ \rho_j(\theta) = \frac{h_j}{\cos(\theta - \alpha_j)}, $$

where $h_j = ||\tilde{x}_s - \tilde{f}_j||_2$ and $\alpha_j = \angle x_j \tilde{x}_s \tilde{f}_j$, where $\tilde{f}_j$ is the foot of the perpendicular from $\tilde{x}_s$ to the edge $x_jx_{j+1}$.

5. Transform the radial variable by $R(\rho)$ defined in section 5 in order to weaken the near singularity due to $\frac{1}{\rho^a}$.

6. Transform the angular variable by $t(\theta)$ in order to weaken the near singularity in $\theta$ which arises from $\rho_j(\theta)$ when $\tilde{x}_s$ is close to the edge of $\tilde{S}$. An efficient transformation can be obtained by letting

$$ \frac{d\theta}{dt} = \frac{1}{\rho_j(\theta)}, $$

which gives

$$ t(\theta) = \frac{h_j}{2} \log \left\{ \frac{1 + \sin(\theta - \alpha_j)}{1 - \sin(\theta - \alpha_j)} \right\}. $$
7. Apply the product Gauss-Legendre quadrature to perform the numerical integration in the transformed variables \( R \) and \( t \) in

\[
I = \sum_j \int_{t(0)}^{t(\tilde{\alpha}_j)} \frac{dt}{\rho_j(\theta)} \int_{R(0)}^{R(\rho_j)} \frac{fJ\rho d\rho}{r^\alpha} dR.
\]

Here, we comment on some details of the above procedure.

The Newton-Raphson's method in Step 1 generally converges within 3 to 4 iterations to give a relative error of \( 10^{-6} \), with the initial solution set to an arbitrary point on \( S_e \), e.g. \((\eta_1, \eta_2) = (0, 0)\), if \( x(\eta_1, \eta_2) \) lies inside the element \( S \) [13, 15]. However, when \( x(\eta_1, \eta_2) \) lies outside \( S \), the method may diverge. This can be circumvented by constraining the solution on the edge of the element for such cases [14].

It was also found that when the point \( x(\eta_1, \eta_2) \) lies outside the original element \( S \) in Step 1, or when it lies inside \( S \) but very close to the edge of \( S \) (namely when \( h_j < d \) in Steps 3 and 4), moving \( x(\eta_1, \eta_2) \) to a nearby point on the edge of \( S \) and redefining \( d \) leads to a considerable reduction of the necessary number of integration points, and hence the computation time [14]-[16].

In Step 2 of the above procedure, the interpolation functions describing the element \( \tilde{S} \) are given by \( \tilde{\phi}_j \), which, in general, is different from the interpolation function \( \phi_j \) of the original element \( S \) [17].

When \( S \) is a (curved) quadrilateral element, \( \tilde{S} \) is a bilinear quadrilateral element whose vertices coincide with the corner nodes of \( S \). (Note that \( x_1, x_2, x_3, x_4 \) and \( \tilde{x}_4 \) are not necessarily coplanar.) The interpolation function defining \( \tilde{S} \) is given by

\[
\tilde{\phi}_{k,l}(\eta_1, \eta_2) = \tilde{\phi}_k(\eta_1)\tilde{\phi}_l(\eta_2),
\]

where \( k, l = -1, 1 \) and

\[
\tilde{\phi}_{-1}(\eta) = \frac{1 - \eta}{2}, \quad \tilde{\phi}_1(\eta) = \frac{\eta + 1}{2}.
\]

When \( S \) is a (curved) triangular element, \( \tilde{S} \) is the planar triangular element whose vertices coincide with the corner nodes of \( S \).

Steps 1 and 2 generally consume less than 1% of the total CPU-time.

In the method, we could also simply work with the sub-triangle \( \tilde{\Delta}_j \) in the parameter space \((\eta_1, \eta_2)\), instead of using the sub-triangle \( \tilde{\Delta}_j \). However, this gives some problems when the element \( S \) has high aspect ratio. Namely, it requires extra integration points for the integration in the angular variable [17] even with the use of an angular variable transformation in the parameter space.
similar to (4.1). This is because the parameter space itself is insensitive to the aspect ratio of the element. Another shortcoming is that the meaning of the source distance $d$ (relative to the element geometry) becomes vague in such cases when one uses it in the radial variable transformation in the parameter space.

We mention here that Koizumi and Utamura [20, 21] also use polar coordinates with further corrections in order to improve accuracy.

The method proposed by Hackbusch and Sauter [7] also employs polar coordinates, but performs the inner integration analytically, while the outer integral is evaluated using the Gauss-Legendre formula. Their method seems promising for planar elements, but theoretical and numerical justification for using it for curved surface elements seems lacking\(^1\).

§5. Optimal Radial Variable Transformations

The choice of the variable transformation $R(\rho)$ for the radial variable is particularly important in the PART method.

For constant planar elements,

$$
\rho \, d\rho = r'^\alpha \, dR \quad \text{or} \quad R(\rho) = \int \frac{\rho}{r'^\alpha} \, d\rho
$$

where $r' := \sqrt{\rho^2 + d^2}$, is equivalent to performing analytical integration in the radial variable, since $r = r'$ in this case.

In [8], we proposed using the above ‘singularity cancelling’ transformation to curved elements, where $r = r'$ does not necessarily hold, in the hope that in the radial variable integration

$$
\int R(\rho_j(\theta)) \frac{fJ\rho}{r'^\alpha} \, d\rho \, dR = \int R(\rho_j(\theta)) \frac{fJ}{r'^\alpha} r'^\alpha \, dR
$$

in equation (4.2), the near singularity due to $\frac{1}{r'^\alpha}$ would be weakened by the term $r'^\alpha$.

Although this has some effect, it was later found [9] that the log $L_2$ transformation

\begin{equation}
(5.1) \quad \rho \, d\rho = r^2 \, dR \quad \text{or} \quad R(\rho) = \log \sqrt{\rho^2 + d^2}
\end{equation}

\(^1\)At p.155 of their paper, it is not explained how to evaluate the second term of $O(h^{\min\ldots})$ in the right hand side of equation (35), which is not generally negligible for curved surface elements.
turns out to be more robust and efficient, in the sense that the transformation works well for all orders of near singularity: $\alpha = 1 \sim 5$.

However, this transformation was found to perform poorly for integrals arising in flux calculations as in equation (2.3), or for model radial variable integrals $I_{\alpha,\delta}$ in (3.1) with $\delta = 2$. The reason is that the $\log L_2$ transformation of equation (5.1) has the property

$$\frac{d\rho}{dR}\bigg|_{\rho=+0} = \infty,$$

so that it induces an infinite derivative at an endpoint of the transformed integrand. This problem can be overcome by the transformation

$$R(\rho) = \log(\rho + d) \quad (\log L_1 \text{ transformation}),$$

which was shown to work efficiently for flux as well as potential kernels over curved surface elements, and also model integrals (3.1) with $\delta = 2$ as well as $\delta = 1$ [11].

In [3], parameter tuning by numerical experiments and theoretical error analysis of the transformation

$$R(\rho) = \log(\rho + ad)$$

showed that the transformation was optimum around $a = 1$, although the transformation is not so sensitive on the parameter $a$.

Another efficient transformation was found to be [16]

$$R(\rho) = (\rho + d)^{-\frac{1}{5}} \quad (L_1^{-\frac{1}{5}} \text{ transformation}).$$

Tables 1 to 4 give some numerical experiment results comparing the effect of the different transformations. The identity transformation in Table 1 means $R(\rho) = \rho$. Tests were performed on the model radial variable integrals of equation (3.1) where $r = r' := \sqrt{\rho^2 + d^2}$ and $\rho_j = 1$. The tables give the minimum number of integration points $n$ required for each method to achieve a relative error of $10^{-6}$ for source distance $d$ varying from 10 to $10^{-3}$.

For extensive numerical experiment results on nearly singular integrals over curved surface elements, see [8, 9], [11]-[17]. The results indicate that the proposed method becomes more efficient, in terms of the necessary integration points and CPU-time, compared to previous methods such as Telles’ [29] when the source distance $d$ is less than 5% of the element size.

For planar elements, the method of Hackbusch and Sauter [7] may require less integration points than ours, since the inner integration is done analytically.

However, their formula includes many terms so that it is not obvious which method is more efficient in terms of CPU-time. For curved surface elements, as mentioned before, the justification for using their method is not clear.

§6. Error Analysis Using Complex Function Theory

The essential nature of the integration in the radial variable which appear in the 3-D potential problem can be modelled by equation (3.1), which is transformed by

\[ I = \int_{R(0)}^{R(\rho)} \frac{\rho^\delta}{r^\alpha} d\rho dR dR \]

where \( r = \sqrt{\rho^2 + d^2} \). This can be further transformed as

\[ I = \int_{-1}^{1} f(x) dx \]

where

\[ f(x) := \frac{\rho^\delta}{r^\alpha} \frac{dR}{dR dx} \]

(6.1)

Here

\[ R := \frac{(R(\rho_j) - R(0))x + R(\rho_j) + R(0)}{2} \]

The following theorem [1, 30, 5] gives the error \( E_n = I - I_n \) of the numerical integration \( I_n = \sum_{j=1}^{n} A_j f(x_j) \) of the integral \( I = \int_{-1}^{1} f(x) dx \).
Theorem 6.1. If $f(z)$ is regular on $K := [-1, 1]$, 

$$E_n(f) = \frac{1}{2\pi i} \oint_{C} \Phi_n(z)f(z)dz$$

where 

$$\Phi_n = \int_{-1}^{1} \frac{dx}{z - x} - \sum_{j=1}^{n} \frac{A_j}{z - a_j}$$

and the contour $C$ is taken so that it encircles the integration points $a_1, a_2, \ldots, a_n$ in the positive (anti-clockwise) direction, and $f(z)$ is regular inside $C$.

The following asymptotic expressions are known for the error characteristic function $\Phi_n(z)$ of equation (6.3) for the Gauss-Legendre rule.

1. For $|z| \gg 1$ [26]

$$\Phi_n(z) = \frac{c_n}{z^{2n+1}} \{1 + O(z^{-2})\}$$

where 

$$c_n = \frac{2^{2n+1}(n!)^4}{(2n)!(2n+1)!}$$

and $c_n \sim \pi 2^{-2n}$ for $n \gg 1$.

2. For $n \gg 1$ [1, 5]

- For all $z \in C$ except for an arbitrary neighbourhood of $K := [-1, 1]$: 

$$\Phi_n(z) \sim 2\pi(z + \sqrt{z^2 - 1})^{-2n-1}$$

- For all $z \in C$ except for an arbitrary neighbourhood of $z = 1$:

$$\Phi_n(z) \sim 2e^{-i\pi} \frac{K_0(2k\zeta)}{I_0(2k\zeta)}$$

where $z = e^{i\pi}\cosh(2\zeta), k = n + \frac{1}{2}$ and $I_0(z), K_0(z)$ are the modified Bessel functions of the first and second kind, respectively.

In the following, let $D := \frac{d}{\rho_j}$, which is the relative source distance.
§6.1. Error analysis for the log $L_2$ transformation

For the log $L_2$ transformation $R(\rho) = \log \sqrt{\rho^2 + d^2}$ of equation (5.1),

$$R(0) = \log d, \quad R(\rho_j) = \log r_j, \quad r_j = \sqrt{\rho_j^2 + d^2}$$

and

$$\rho(R) = (e^{2R} - d^2)^{\frac{1}{2}}$$

so that

$$f(z) = a \left\{ e^{(-\log \Delta')z} - \Delta' \right\} \frac{\delta - 1}{2} e^{\frac{2\pi}{(-\log \Delta')z}}$$

where

$$\Delta' := \frac{d}{r_j} = \frac{\sqrt{1 + D^2}}{r_j} \frac{D}{\sqrt{1 + D^2}} < 1, \quad -\log \Delta' > 0, \quad a := \frac{(-\log \Delta')}{2} (r_j d)^{\frac{\delta - 1}{2}} > 0.$$

Case: $\delta = \text{odd}$

Since $\frac{\delta - 1}{2}$ is a non-negative integer, $f(z)$ is regular except for $z = \infty$.

Hence, taking $C = \{ z \mid |z| = R, R \to \infty \}$ as the contour in Theorem 6.1 and using the asymptotic expression of equation (6.4) for $|z| \gg 1$, we obtain

$$E_n(f) = \frac{c_n}{2\pi i} \int_C f(z) z^{-2n-1} dz = c_n a_{2n}$$

where

$$f(z) = \sum_{k=1}^{\infty} a_k z^k,$$

so that

$$E_n(f) \sim D^{\frac{\delta + 1 - n}{2}} \left( \frac{\log D}{n} \right)^{2n} \sim O(n^{-2n}).$$

This corresponds well with numerical results for the integration of potential kernels using the log $L_2$ transformation [12].

Case: $\delta = \text{even}$

When $\delta$ is even, as in the case of flux kernels, $f(z)$ of equation (6.7) has a branching point singularity at

$$z_m = -1 + i \frac{2\pi m}{(-\log \Delta')}, \quad (m : \text{integer}).$$
In this case, \( f(z) \) has a singularity at the endpoint \( z = -1 \) of the interval \( K = [-1, 1] \). However, we can apply Theorem 6.1 by taking the contour as \( C = \varepsilon + l + C_x + l_- \), where \( \varepsilon \) is an ellipse

\[
|z + \sqrt{z^2 - 1}| = \sigma, \quad \sigma > 1,
\]

with an anti-clockwise direction, which has \( z = \pm 1 \) as its focii, and the singularities \( z_1, z_{-1} \) are outside the ellipse. \( l_+ \) and \( l_- \) are the real segment \((x_0, -1 - \varepsilon)\) in the positive and negative directions, respectively. \( x_0 = \frac{1}{2} \left( \sigma + \frac{1}{\sigma} \right) \) is the major axis of \( \varepsilon \). \( C_x \) is a circle of radius \( 0 < \varepsilon \ll 1 \) in the clockwise direction with its centre at \( z = -1 \), so that \( C \) escapes the singularity at \( z = -1 \).

It turns out that the most significant contribution to \( E_n(f) \) of equation (6.2) comes from the branch lines \( l_+ \) and \( l_- \), i.e.,

\[
E_n(f) \sim E_{l_+, l_-} \sim (-\log D)^{\frac{\delta + 1}{2}} D^{\delta + 1 - \alpha} n^{-\delta - 1} \sim O(n^{-\delta - 1}),
\]

where the asymptotic expression (6.6) is used [12, 13]. This matches well with numerical results for the integration of the flux kernels, which give \( E_n(f) \sim O(n^{-3}) \), where \( \delta = 2 \).

§6.2. Error analysis for the log \( L_1 \) transformation

For the log \( L_1 \) transformation \( R(\rho) = \log(\rho + d) \), we have

\[
R(0) = \log d, \quad R(\rho_j) = \log(\rho_j + d)
\]

and

\[
\rho(R) = e^R - d, \quad \frac{d\rho}{dR} = e^R,
\]

so that \( f(x) \) of equation (6.1) is given by

\[
f(z) = \frac{b(w - 1)^{\delta}w}{\{w - (1 - i)^2\}^{\frac{\delta}{2}} \{w - (1 + i)\}^{\frac{\delta}{2}}}
\]

where

\[
w := e^{\frac{\delta + 1}{2} (-\log \Delta)}, \quad \Delta := \frac{D}{1 + D} < 1, \quad -\log \Delta > 0, \quad b := \frac{(-\log \Delta)}{2} d^{\delta - \alpha + 1}.
\]

\( f(z) \) has singularities (branching when \( \alpha = \text{odd} \)) at

\[
z = z_{\pm_m} := -1 + \frac{\log 2}{(-\log \Delta)} + i \frac{(4m \pm \frac{1}{2}) \pi}{(-\log \Delta)}, \quad (m : \text{integer}).
\]
As the contour $C$ in Theorem 6.1, we take the ellipse $\varepsilon_\sigma$ of equation (6.8) which passes through the point
\[ z_t := -1 + \frac{\log 2}{(-\log \Delta)} + i \frac{\pi t}{2(-\log \Delta)} \quad (0 < t < 1), \]
so that the singularities $z^\pm_0$ nearest to the endpoint $z = -1$ lie outside $C$. Hence, there are no singularities of $f(z)$ inside $C = \varepsilon_\sigma$.

Using the asymptotic expression of equation (6.5) for $n \gg 1$ in equation (6.2), we obtain
\[ (6.10) \quad |E_n(f)| \leq \frac{l(\varepsilon_\sigma)}{\sigma^{2n+1}} \max_{z \in \varepsilon_\sigma} |f(z)| < 2\pi \sigma^{-2n} \max_{z \in \varepsilon_\sigma} |f(z)| \]
where $l(\varepsilon_\sigma)$ is the length of the ellipse $\varepsilon_\sigma$ [6].

For the ellipse $\varepsilon_\sigma$ passing through $z_t$, we have
\[ (6.11) \quad \sigma = \frac{c}{2} p + \sqrt{\frac{c^2}{4} p^2 - p \log 2 + 1} \]
\[ + \sqrt{\frac{c^2}{2} p^2 - p \log 2 + \frac{c^2}{4} p^2 - p \log 2 + 1} \]
where
\[ p := \frac{1}{(-\log \Delta)} \]
and
\[ c := \sqrt{(\log 2)^2 + \left(\frac{\pi t}{2}\right)^2} \quad (0 < t < 1). \]

$\sigma = \sigma(D,t)$ is a strictly increasing with respect to $D$.

Since $|f(z_t)| = +\infty$, for $|1 - t| \ll 1$, we have
\[ \max_{z \in \varepsilon_\sigma} |f(z)| \sim |f(z_t)| \sim 2^{-\frac{2}{\alpha^2}} \alpha^{-\frac{\pi}{4}} d^{\delta - \frac{\alpha}{2}} (-\log \Delta)(1 - t)^{-\frac{\alpha}{2}} \]
from equation (6.9).

Since we are interested in the cases $\alpha = 1, 3, 5$, $(1 - t)^{-\frac{\alpha}{2}} \leq 10$ implies $t \leq 0.6$. Hence, we let $t = 0.6$, so that equation (6.12) gives $\sigma = 1.31, 1.40, 1.63$ for the nearly singular cases $D = 10^{-3}, 10^{-2}, 10^{-1}$, respectively.

To sum up, for the log $L_1$ transformation $R(\rho) = \log(\rho + d)$, the numerical integration error is estimated by
\[ (6.12) \quad E_n(f) \sim (-\log D) D^{\delta + 1 - \alpha} \sigma^{-2n} \]
where $\sigma = 1.31 \sim 1.63$ for $D = 10^{-3} \sim 10^{-1}$. This estimate was found to correspond well with numerical results [12, 13].

§6.3. Error analysis for the $L_{1-\frac{1}{m}}$ transformation

For the $L_{1-\frac{1}{m}}$ transformation $R(\rho) = (\rho + d)^{-\frac{1}{m}}$ ($m > 1$), we have

$$R(0) = d^{-\frac{1}{m}}, \quad R(\rho_j) = (\rho_j + d)^{-\frac{1}{m}},$$

and

$$\rho(R) = R^{-m} - d, \quad \frac{d\rho}{dR} = -mR^{-m-1},$$

so that $f(z)$ of equation (6.1) is given by

$$(6.13) \quad f(z) = A \left\{ (z - z_1)^m - \alpha_1 m \right\}^{\delta} (z - z_1)^{(\alpha - \delta - 1)m - 1}
\times \left\{ (z - z_1)^m - 2^{-\frac{1}{m}} e^{i\alpha_1 m} \right\}^{-\frac{1}{2}} \left\{ (z - z_1)^m - 2^{-\frac{1}{m}} e^{-i\alpha_1 m} \right\}^{-\frac{1}{2}},$$

where

$$z_1 := \frac{1 + \Delta}{1 - \frac{1}{m}}, \quad \alpha_1 := -\frac{2}{1 - \frac{1}{m}}, \quad \Delta := \frac{D}{1 + D},$$

$$A := m (-1)^{\delta - m} 2^{m-\frac{1}{2}} (\rho_j D)^{\delta - \alpha + 1} (1 - \frac{1}{m})^{-m}.$$

When $m \in \mathbb{N}$, the singularities of $f(z)$ are situated at

$$z = z_k^+ := z_1 + \frac{2^{1 - \frac{1}{m}}}{1 - \frac{1}{m}} e^{i \left( 1 + \frac{1}{m} + \frac{2\pi}{m} \right) k}$$

where $k \in \mathbb{Z}$. For $\alpha = \delta = 1$ ($u^*$) and $\alpha = 3, \delta = 2$ ($\partial u^*/\partial x_s$), $z = z_1$ is also a singularity.

As the contour $C$ in Theorem 6.1, again we take the ellipse $\varepsilon_\sigma$ of equation (6.8) which does not have any singularities inside. Also, we employ the asymptotic expression of equation (6.5) for $n \gg 1$ in equation (6.2) to obtain equation (6.10).

It can be shown [16] that for $m = 5, D > D^* \sim 3 \times 10^{-7}$, the ellipse described by equation (6.8) passing through $z = Z_0^-$ is smaller than the one passing through $z = Z_1$, and hence the former is the critical one. Hence, for the case $D > D^*$, we will consider the ellipse $\varepsilon_\sigma$ of equation (6.8) passing through the point:
\[ z_t := x_0 + it y_0 = \frac{1 + \Delta^\frac{1}{4m} - 2^{1/2} m \cos \frac{\pi}{4m} + i \frac{2^{1/2} m \sin \frac{\pi}{4m}}{1 - \Delta^\frac{1}{4m}} t}{1 - \Delta^\frac{1}{4m}} \quad (0 < t < 1) \]

which is located just below the singular point \( z_0^* = x_0 + iy_0 \).

Note that the size \( \sigma \) of the ellipse of equation (6.8) passing through a point \( z = x + iy \) is given by \( \sigma = \gamma + \sqrt{\gamma^2 - 1} \) where
\[
\gamma := \frac{\sqrt{(x + 1)^2 + y^2} + \sqrt{(x - 1)^2 + y^2}}{2}.
\]

Hence, the size of the ellipse of equation (6.8) passing through \( z_t \) can be determined as a function \( \sigma(D, t) \) of \( D \) and \( t \), where \( \sigma(D, t) \) is strictly increasing with respect to \( D \).

Since \( |f(z)| = +\infty \), for \( |1 - t| \ll 1 \), we have
\[
\max_{z \in \Gamma_D} |f(z)| \sim |f(z_t)| \sim m^{1 - \frac{1}{2\gamma} - \frac{1}{2m} - \frac{1}{2m}} (\rho D)^{\delta - \alpha + 1} \left( 1 - \Delta^\frac{1}{4m} \right) \left( \sin \frac{\pi}{4m} \right)^{-\frac{1}{2}} (1 - t)^{-\frac{1}{2}}
\]
from equation (6.13).

Since we are interested in the cases \( \alpha = 1, 3, 5 \), \( (1 - t)^{-\frac{1}{2}} \leq 10 \) implies \( t \leq 0.6 \). Hence, we let \( t = 0.6 \), so that we have \( \sigma = 1.41, 1.48, 1.67 \) for the nearly singular cases \( D = 10^{-3}, 10^{-2}, 10^{-1} \), respectively.

To sum up, for the \( L_1 \) transformation \( R(\rho) = (\rho + d)^{-\frac{1}{2}} \), the numerical integration error is estimated by
\[ E_n(f) \sim (1 - D^\frac{1}{2}) D^{\delta + 1 - \alpha} \sigma^{-2n} \]
where \( \sigma = 1.41 \sim 1.67 \) for \( D = 10^{-3} \sim 10^{-1} \), which is slightly better than the corresponding estimate for the \( \log L_1 \) transformation of equation (6.12). This estimate was also found to correspond well with numerical results [15, 16].

### §6.4. Error analysis of the identity transformation

Finally, as a comparison, we analyze the integration error when the identity transformation \( R(\rho) = \rho \) is used. In this case,
\[ f(z) = B(z + 1)^{\delta} (z - z_1)^{-\frac{\pi}{2}} (z - \overline{z_1})^{-\frac{\pi}{2}} \]
where
\[ B := \left( \frac{\rho_1}{2} \right)^{\delta + 1 - \alpha}, \quad z_1 := -1 + 2Di. \]
We take the ellipse of equation (6.8) passing through
\[ z_t := -1 + 2Dt \quad (0 < t < 1), \]
so that
\[ \sigma = \sqrt{1 + (Dt)^2} + \sqrt{2Dt\{\sqrt{1 + (Dt)^2} + Dt\} + Dt}. \]
Since
\[ \max_{z \in \varepsilon\sigma}|f(z)| \sim |f(z_t)| \sim 2^{-\alpha-1}(\rho_j)^{\delta+1-\alpha}D^{\delta-\frac{3\rho_j}{2}}|1-t|^{-\frac{d}{2}}, \]
leaving \( t = 0.6 \) so that \((1-t)^{-\frac{d}{2}} \sim 10\) gives
\[ E_n(f) \sim D^{\delta-\frac{3\rho_j}{2}}\sigma^{-2n} \]
where \( \sigma = 1.04, 1.12, 1.42 \) for \( D = 10^{-3}, 10^{-2}, 10^{-1}, \) respectively. These error estimates were also found match well with numerical experiments [13, 15].

§6.5. Summary of the error analysis

Summing up the error analysis, we have the following.

For the identity transformation \( R(\rho) = \rho, \)
\[ E_n(f) \sim D^{\delta-\frac{3\rho_j}{2}}\sigma^{-2n} \]
where \( \sigma = 1.04, 1.12, 1.42 \) for \( D = 10^{-3}, 10^{-2}, 10^{-1}, \) respectively.

For the log L_2 transformation \( R(\rho) = \log \sqrt{\rho^2 + d^2}, \)
- when \( \delta = \text{odd}, \)
  \[ E_n(f) \sim D^{\frac{\delta+1}{2}n} \left( \frac{\log D}{n} \right)^{2n}, \]
- when \( \delta = \text{even}, \)
  \[ E_n(f) \sim (-\log D)^{\frac{\delta+1}{2}}D^{\delta+1-\alpha_n^{\delta-1}}. \]

For the log L_1 transformation \( R(\rho) = \log(\rho + d), \)
\[ E_n(f) \sim (-\log D)D^{\delta+1-\alpha}\sigma^{-2n} \]
where \( \sigma = 1.31, 1.40, 1.63 \) for \( D = 10^{-3}, 10^{-2}, 10^{-1}, \) respectively.
For the $L_1^{-\frac{1}{2}}$ transformation $R(\rho) = (\rho + d)^{-\frac{1}{2}}$,

$$E_n(f) \sim (1 - D) D^{\delta + 1 - \alpha} \sigma^{-2n}$$

where $\sigma = 1.41, 1.48, 1.67$ for $D = 10^{-3}, 10^{-2}, 10^{-1}$, respectively.

Thus, the log $L_1$ transformation and the $L_1^{-\frac{1}{2}}$ transformation are predicted to be the most efficient radial variable transformations among the above, where the latter is slightly better than the former.

These error estimates were found to match well with numerical experiments.

The theoretical error estimates also give a clear insight regarding the optimization of the radial variable transformation $R(\rho)$ for nearly singular integrals arising in boundary element analysis.

To be more precise, the singularities $\rho_{\pm} = \pm d \in C$, inherent in the near singularity of

$$\frac{1}{r^\alpha} = \frac{1}{\sqrt{\rho^2 + d^2}},$$

are mapped to $R(\rho_{\pm})$ by the radial variable transformation $R(\rho)$. Then, $R(\rho_{\pm})$ are mapped to $z_{\pm} = x(R(\rho_{\pm}))$ by the transformation

$$x = \frac{2R - \{R(\rho_1) + R(0)\}}{R(\rho_1) - R(0)},$$

in the process of mapping the interval $R : [R(0), R(\rho_j)]$ to the interval $x : [-1, 1]$ in order to apply the Gauss-Legendre rule.

The error analysis in this section showed that the numerical integration error is governed by the maximum size $\sigma$ of the ellipse $\varepsilon_\sigma$

$$|z + \sqrt{z^2 - 1}| = \sigma, \quad (\sigma > 1)$$

in the complex plane which does not include the singularities $z_{\pm}$ inside.

Therefore, roughly speaking, the optimum radial variable transformation $R(\rho)$ is the transformation which maps the singularities $\rho_{\pm} = \pm d$, inherent in the near singularity, to $z_{\pm} = x\{R(\rho_{\pm})\}$ which are as far away as possible from the real interval $z : [-1, 1]$, allowing an ellipse $\varepsilon_\sigma$ of maximum size $\sigma$.

§7. On the Use of the Double Exponential Transformation

The double exponential (DE) formula [31] is known to be a powerful method for singular integrals and have also been used for nearly singular integrals in the boundary element method [18, 19]. In [10, 13, 15], we applied the
single (SE) and double exponential (DE) formulas to the model radial variable integrals of equation (3.1), in combination with the truncated trapezium rule. However, they were not as efficient as the log $L_1$ and the $L_1^{-\frac{d}{2}}$ transformations combined with the Gauss-Legendre rule.

Nevertheless, in the context of automatic integration, methods based on the double exponential transformation are attractive. This is because they are based on the trapezium rule with equal step size, so that one can keep on adding integration points, making use of previous integration points, until sufficient accuracy is achieved. In [22]-[24], we showed by theoretical error analysis and numerical experiments on the model radial variable integrals of equation (3.1), that the log $L_2$ transformation $R(\rho) = \log \sqrt{\rho^2 + d^2}$ in combination with the double exponential transformation gives promising results when using the trapezium rule. These transformations alone, which were not particularly attractive, proved to be useful when combined. This is because the double exponential transformation has the effect of removing the problematic end-point singularity inherent in the log $L_2$ transformation.

To be more specific, the procedure applied to the model integrals of (3.1) is described as follows.

**Step 1:** Apply the log $L_2$ transformation:

$$R(\rho) = \log \sqrt{\rho^2 + d^2}$$

and let

$$x = \frac{2R - \{R(\rho_j) + R(0)\}}{R(\rho_j) - R(0)}.$$ 

Then, the integrals of (3.1) become

$$I = \int_{-1}^{1} \frac{\rho^2}{\rho^2 + d^2} \frac{dR}{dx} \frac{dx}{dx} = \int_{-1}^{1} b \left( a^2 - \frac{1}{a} \right) \frac{dx}{dx} a^{\frac{a}{2}} \int_{-1}^{1} g(x) dx,$$

where

$a = \sqrt{\frac{\rho_j^2 + d^2}{a}}, \quad b = \frac{\log a}{2 \left( \sqrt{\rho_j^2 + d^2} \cdot d \right)}^{\frac{a}{2} + \frac{1}{2}}$.

**Step 2:** Apply the Double Exponential(DE) transformation: $x = \tanh \left( \frac{\pi}{2} \sinh u \right)$. Then,

$$I = \int_{-\infty}^{\infty} g(x) \frac{dx}{du} du = \int_{-\infty}^{\infty} f(u) du,$$

where

$$f(u) = g \left( \tanh \left( \frac{\pi}{2} \sinh u \right) \right) \frac{\pi}{2} \cosh u \frac{1}{\cosh^2 \left( \frac{\pi}{2} \sinh u \right)}.$$
Step 3: Approximate by the trapezium rule:

\[ I \sim h \sum_{k=\infty}^{\infty} f(kh), \]

with an appropriate truncation.

The numerical integration of Step 3 can be done automatically as follows:

**Step 3.1:** Determine the integration interval \([a, b]\) and the step size \(h\) for approximating the integral of equation (7.1), and compute according to the \(n\) point formula:

\[
I_h = h \left\{ \frac{1}{2} f(a) + \sum_{j=1}^{n-1} f(a + jh) + \frac{1}{2} f(b) \right\},
\]

where \(h = \frac{b - a}{n - 1}\).

**Step 3.2:** Halve the discretization width \(h\) and compute \(I_{h/2}\).

**Step 3.3:** Determine whether the convergence condition:

\[
\left| \frac{I_{h/2} - I_h}{I_{h/2}} \right| < \epsilon
\]

is satisfied.

If it is satisfied, end. If it is not satisfied, let \(h = h/2\) and go to Step 3.2.

Table 5 and 6 give numerical experiment results comparing the DE transformation with the log L₂-DE transformation, showing the effectiveness of combining the log L₂ and the DE transformations. Tests were performed on the same model radial variable integrals as in Table 1 to 4, with the same conditions.

In [24], error estimates were also derived for the above transformations and it was shown that combining the log L₂ transformation with the DE transformation has the effect of increasing the distance between the singularity and the real axis, thus improving the accuracy of the quadrature.

### §8. Conclusions

In this paper we reviewed variable transformation methods for evaluating nearly singular integrals over curved surfaces arising in the three-dimensional boundary element method, which were proposed by the author and co-workers. Particularly, we showed that certain nonlinear radial variable transformations play an important role in the methods, and that error analysis using complex function theory yields a clear insight regarding the optimization of the radial variable transformation.
